A comparison of the rough sphere rotational diffusion model with experimental results for liquid methyl iodide

Dane R. Jones, S. L. Whittenburg, and C. H. Wang

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

(Received 2 April 1976)

The rotational motion of molecules in the liquid state has been described using several models. Chandler has recently developed a theory which describes rotational motion in terms of a system of rough hard spheres interacting through binary collisions. This model, which provides a microscopic derivation of Gordon's J-diffusion model, has been tested against molecular dynamics results and spin–spin and spin–lattice NMR relaxation time results. To our knowledge, no detailed comparisons have been made between Chandler's
theory and Raman and infrared experimental results. It is the purpose of this note to present such a comparison. We use methyl iodide for testing the theory, as both infrared and Raman data for this molecular liquid are accurately known.

Chandler’s rough hard sphere model pertains strictly to a system of spherical particles undergoing instantaneous collisions. As a result of a collision, one particle transfers angular momentum to the particle with which it collides. For smooth spheres, the collisions are still instantaneous but no transfer of angular momentum takes place. A realistic model for nonspherical molecules, such as CH₃I, would probably lie between these extremes of “smooth” and “rough”, as was pointed out by Chandler. In his paper, Chandler gives theoretical expressions for the rotational correlational functions C₁(t) and C₂(t) and the zero-frequency relaxation times τ₁ and τ₂ which correspond to the experimental infrared and Raman zero-frequency rotational relaxation times, respectively. The final forms of the equations are

\[ \tau_1 = \int_0^\infty C_1(t) dt = \tau_w x e^x E_1(x) \left[ 1 - x e^x E_1(x) \right] \]  

(1)

and

\[ \tau_2 = \int_0^\infty C_2(t) dt = \tau_w \left[ 1 + 3 y e^y E_1(y) \right] / 4 \left\{ 1 - \frac{3}{2} \left[ 1 + 3 y e^y E_1(y) \right] \right\} \]  

(2)

where \( x = 1/2 \rho \sigma^3 kT, \) \( y = 1/8 \rho \sigma^3 kT, \) I is the moment of inertia, T is the absolute temperature, and \( k \) is Boltzmann’s constant. \( \tau_w \) is essentially the angular momentum correlation time and is related to the Enskog relaxation time \( \tau_P \) through the relation \( \tau_1 = a \tau_P^2 \), where \( a \) is the roughness of the hard sphere. For perfectly smooth hard spheres \( a = 0 \), and for perfectly rough hard spheres \( a = \left[ 4 \sigma^2 / (md^2) + 1 \right]^{1/2} \), where \( m \) is the molecular mass and \( d \) is the molecular diameter. \( \tau_P \) is given by

\[ \tau_P^2 = \frac{5}{3} \rho k T / \rho \sigma^3 g \]  

where \( \rho \) is the particle density, \( g \) is the contact value of the hard sphere radial distribution function, equals \( (2 - \eta) / 2 (1 - \eta)^3 \) with \( \eta \) the packing fraction, equal to \( \rho / 6 \rho \sigma^3 \). The function \( E_1(x) \) is given by

\[ E_1(x) = \int_x^\infty e^{-u} du / u \]  

(4)

Chandler compared the predictions of his theory to molecular dynamics results for liquid nitrogen. Nitrogen is a linear molecule with a length-to-width ratio of about 1.3. The theoretical values of \( \tau_2 \) agreed with the molecular dynamics results for a roughness of 0.43 (the perfectly rough sphere roughness for \( N_2 \) is about 0.83). The theoretical \( \tau_1 \) values were generally lower than the molecular dynamics results. O’Dell and Berne have performed molecular dynamics experiments for a rough sphere fluid and compared the results to the predictions of Chandler’s theory. The theoretical relaxation times were consistently larger than the molecular dynamics times. DeZwann and Jonas have studied CCl₄F and SF₆ using spin-echo and spin-lattice NMR techniques. From the spin-lattice relaxation time measurements, experimental angular momentum correlation times were obtained. Hard sphere diameters were calculated from the density dependent \( \tau_1 \) values and these diameters were used in a calculation, using Chandler’s model, of the self-diffusion constants. The theoretical self-diffusion constants were in agreement with experimental values obtained from spin-echo measurements, when the hard sphere diameters were allowed to vary with temperature.

We have calculated theoretical rotational relaxation times for liquid CH₃I at 283.7 K for a wide range of \( \tau_w \) values using Eqs. (1) and (2). The results are given in Fig. 1. Experimental \( \tau_1 \) (infrared) and \( \tau_2 \) (Raman) single particle rotational relaxation times for methyl iodide have been reported by several authors. Jones, Andersen, and Pecora reported \( \tau_1 \) and \( \tau_2 \) values of 3.1 \( \pm \) 0.4 and 1.5 \( \pm \) 0.4 ps, respectively, at 283, 7 K. These values were obtained from the exponential part of the corresponding correlation functions. Zero-frequency relaxation times obtained from the experimental correlation functions of Jones et al. were the same as those obtained from the exponential part of the correlation functions within experimental uncertainty. Theoretical \( \tau_1 \) and \( \tau_2 \) relaxation times in agreement with the experimental values can be obtained only for a very small value of \( \tau_w \). For \( \tau_w \approx 2.5 \times 10^{-15} \) s, the plots in Fig. 1 yield \( \tau_1 \) and \( \tau_2 \) values of 2.9 and 1.6 ps, respectively. These theoretical rotational relaxation times seem to agree fairly well with the experimental values given above. However, such a small \( \tau_w \) value does not appear to be physically reasonable. Lyerla, Grant, and Wang reported an experimental angular momentum relaxation time for CH₃I of 0.12 ps, which is a factor of 50 greater than the \( \tau_w \) obtained from Fig. 1. To investigate further, we used the \( \tau_w = 2.5 \times 10^{-15} \) s value and various values of the molecular diameter \( d \) to calculate values for the packing fraction \( \eta \). Enskog

$\tau_w = \frac{\tau_E}{2\pi}$. $a^2 = [4(1/m^2)+1]^1$.

Relaxation time $\tau_E$, and roughness $a$. We also calculated the roughness of a perfectly rough hard sphere for the different diameters. The results are given in Table I. For diameters less than 5.5 Å, the $a$ values calculated from $\tau_E$ and $\tau_w$ are much larger than the roughness for the corresponding perfectly rough hard sphere. For physically reasonable roughness and diameter values, the packing fraction is much too great; e.g., for the most compact packing, face-centered cubic, $\eta = 0.74$.

Thus, this small value of $\tau_w$, while giving $\tau_E$ and $\tau_w$ values in agreement with experimental results, is physically unreasonable. The theoretical $\tau_w$ value for $\tau_w = 4 \times 10^{-12}$ s agrees with the experimental value, but the corresponding theoretical $\tau_E$ value is a factor of 20 too small. We conclude that there is no physically acceptable value of $\tau_w$ which can explain the experimental $\tau_E$ and $\tau_w$ data of methyl iodide. It would be interesting to use high pressure to investigate the density dependence of $\tau_E$ and $\tau_w$ in an attempt to learn more about the nature of molecular motion in liquids composed of nonspherical molecules.

We are grateful to Professor D. Chandler for a critical review of the manuscript and for very valuable discussions. We also acknowledge the Donors of The Petroleum Research Fund, administered by the American Chemical Society, for the support of this research.

Barriers to internal rotation obtained by pseudopotential calculations

Carl S. Ewig and John R. Van Wazer

Department of Chemistry, Vanderbilt University, Nashville, Tennessee 37235

(Received 1 March 1976)

In recent studies,¹⁻⁴ we have shown that the use of our molecular pseudopotential theory gives results that are comparable to those obtained with the same basis set in a full SCF calculation for all the molecular properties we have investigated. Here we describe the application of this method (the NOCOR procedure) to the calculation of barriers to molecular internal rotation.

The rotational barriers for a valence isoelectronic series—ethane, methyldisilane, methylgermane, and methylstannane—are presented in Table I, in which the results of the NOCOR method are seen to compare well with those obtained by an equivalent full SCF calculation and with the best experimental values. Both the pseudopotential and the full SCF calculations were carried out in a minimum–Slater basis set with each Slater orbital being expanded into a set of four Gaussian functions. The Slater exponents used in these calculations were molecularly optimized for ethane⁷ and methyldisilane.⁸ For the two remaining molecules, the Slater exponents for the methyl hydrogens and the carbon atoms were chosen to be equal to those obtained for the methyl group in methyldisilane. Atom-optimized Slater exponents were employed for the germanium and tin atoms, and their attached hydrogens were assumed to have an exponent of 1.0. On going from the staggered to the eclipsed
