Received 13 May 1998/Accepted 23 July 1998

A DNA-based, direct method for initial characterization of the total bacterial community in ileum and cecum of the chicken gastrointestinal (GI) tract was developed. The efficiencies of bacterial extraction and lysis were >95 and >99%, respectively, and therefore the DNA recovered should accurately reflect the bacterial communities of the ileal and cecal digesta. Total bacterial DNA samples were fractionated according to their percent G+C content. The profiles reflecting the composition of the bacterial community were reproducible within each compartment, but different between the compartments of the GI tract. This approach is independent of the culturability of the bacteria in the consortium and can be used to improve our understanding of how diet and other variables modulate the microbial communities of the GI tracts of animals.

The microbiology of the gastrointestinal (GI) tracts of farm animals has long been of interest for reasons of both food safety and animal nutrition and health. Attempts are being made to bolster host defenses by using feed ingredients which favor the growth of bacteria generally regarded as beneficial. Typical modulators of GI tract ecology are prebiotics (e.g., oligosaccharides [25]) and probiotics (e.g., lactobacilli and bifidobacteria [5, 24, 25]). Understanding of the mode of action and development of effective products would be greatly assisted by reliable tools with which to monitor the composition of the microbial community in the GI tract.

Molecular techniques have been employed to monitor for the presence of specific bacterial pathogens in chicken digesta samples (2, 6, 16, 26). In order to place findings from such single-species studies in perspective, some knowledge of the total bacterial community composition of this system must be obtained. However, direct analyses (i.e., analyses that are not based on culturability) of bacterial community structure in the various compartments of the chicken GI tract have not yet been performed. In other complex environments, DNA-based community-level molecular analyses have been used to obtain information on microbial community diversity, structure, and function (10, 12, 20, 21, 27, 30, 36). In this report, we show for the first time essentially quantitative recovery and lysis of the bacterial fraction from the distal part of broiler chicken small intestine (ileum) and cecum and also purification of total DNA representing the bacterial community, a requisite step for DNA-based community analyses. We also provide an initial depiction of the total bacterial community in these two chicken GI tract compartments obtained by DNA-based profiling.

**Bacterial extraction.** Broiler chickens were raised in cages and unless otherwise indicated were fed a standard wheat-based diet with no antibiotics. The birds were killed by cervical dislocation, and the ileum and cecum were immediately removed and dissected. All digesta samples were kept on ice and processed further within 2 h. Quantitative bacterial recovery and lysis are prerequisites for all subsequent comprehensive DNA-based community analyses. Therefore, these protocols were carefully developed, and their efficiencies were demonstrated. Digesta samples from the different compartments of the broiler chicken digestive tract were found to vary in composition, the amount of material present, and bacterial density. Bacterial numbers in the ileum, the distal part of small intestine, were typically between 10 10 and 10 11 per g of digesta, and the bulk of the dry matter was undigested feed particles, which had to be eliminated prior to bacterial lysis. This was accomplished through the five-cycle differential centrifugation process. Seven grams of ileal digesta was suspended in 200 ml of wash buffer (50 mM sodium phosphate buffer [pH 8], 0.1% Tween 80). The suspensions were then shaken for 20 min on a reciprocating horizontal platform shaker at 100 oscillations/min at room temperature. Undigested feed particles were removed from the suspension by low-speed centrifugation at 200 x g for 15 min. The supernatant was carefully transferred to a clean flask and kept on ice. The digesta pellet was again suspended in wash buffer, the differential centrifugation process was repeated for a total of five rounds, and samples of both the suspended digesta and the low-speed supernatant were taken before each round for microscopic enumeration of bacteria. The bacteria in the pooled supernatants were collected by centrifugation at 30,000 x g for 15 min at room temperature. In the dual cecal compartments, solid feed particles were absent and bacterial densities were typically between 10 10 and 10 11 per g of digesta. For efficient bacterial recovery and lysis from this compartment, it was important to remove the viscous polysaccharides and other soluble compounds interfering with these procedures. This was achieved by a four-cycle dilution and washing process. Cecal samples (1 g) were suspended in 30 ml of wash buffer and then shaken for 10 min on a reciprocating horizontal platform shaker at moderate speed at room temperature. The resulting suspension was subjected to centrifugation at 30,000 x g for 15 min to collect the bacterial fraction. The pellet was resuspended and washed three more times in 30 ml of fresh wash buffer, and samples of the suspended bacteria were taken at each step for direct microscopic enumeration. Microscopic enumeration of bacte-
Bacterial lysis and DNA recovery. Effective lysis of complex mixtures of bacteria often requires a combination of various treatments known to be effective for lysing individual bacterial populations (11). To maximize the lysis efficiency for the bacterial populations present in chicken digesta, the salient steps from a variety of cell lysis protocols were combined to obtain the general bacterial lysis protocol. Samples of the bacterial fractions (0.3 g of cecal bacterial pellet and 0.7 g of ileal bacterial pellet) were resuspended in 3 ml of TE buffer (10 mM Tris [pH 8], 1 mM EDTA). These suspensions were subjected to five freeze-thaw cycles of incubation at −70°C for 60 min followed by 40°C for 15 min. Lysozyme was then added to each sample as 0.7 ml of a 200-kg/ml stock solution (in TE buffer) followed by incubation at 37°C for 3 h. After the addition of 0.2 ml of sodium dodecyl sulfate (10% [wt/vol]) and 20 µl of proteinase K solution (20 µg/ml in TE buffer), the mixture was incubated at 37°C for an additional hour. Following this incubation, 0.72 ml of 5 M NaCl, 0.6 ml of 10% CTAB (hexade- cyltrimethyl ammonium bromide) in 0.7 M NaCl, and 1 g of 1,000-µm-diameter glass beads (Sigma Chemical Company, St. Louis, Mo.) were added. The mixtures were then incubated at 65°C for 20 min with vortexing for 30 s after every 5 min. Samples of the suspended bacterial fraction were taken before and after lysis to assess lysis efficiency by direct microscopic enumeration of bacteria. The cell lysis was extracted with an equal volume of chloroform-isooamyl alcohol (24:1) and then subjected to centrifugation at 6,000 × g for 10 min at room temperature to separate the aqueous and organic phases. After transfer of the aqueous phase to a clean Corex test tube, the DNA was precipitated by addition of 0.6 volume of 100% isopropanol and incubation for 1 h at room temperature. The

**FIG. 1.** Cell removal from digesta material (■) and cumulative recovery (□) of bacteria from ileal digesta samples during the bacterial recovery process. The data were obtained by direct microscopic enumeration of bacterial cells in the supernatant following each round of differential, low-speed centrifugation. Percent removal is based on the number of cells present in the starting ileal digesta sample. Error bars indicate 1 standard error of the mean (n = 4).

**FIG. 2.** Profiles of the bacterial community in ileal (A) and cecal (B) digesta material from 4-week-old chickens. Data were obtained as a continuous stream from the UV absorbance flow cell and are presented as percent G + C content versus relative abundance. The solid line in each panel indicates the mean of two replicate samples. The shaded areas in each panel indicate the standard error of the mean.
precipitated DNA was collected by centrifugation at 10,000 \times g for 15 min at room temperature. The DNA pellet was washed briefly with 70% ethanol, vacuum dried, and dissolved in 2 ml of TE buffer. The extracted DNA was then purified by two rounds of cesium chloride-ethidium bromide equilibrium gradient centrifugation as described by Holben (9). The DNA bands from these gradients were subjected to ethidium bromide extraction, desalting, and concentration of DNA by ethanol precipitation, also as described by Holben (9). DNA concentration and purity were estimated based on $A_{260/280}$.

Microscopic analysis was used to monitor the efficiency of lysis of the bacterial fractions obtained from ileal and cecal digesta. Direct microscopic counts before and after the lysis procedure indicated that >99% of the bacteria in both the ileal and cecal bacterial fractions were lysed (data not shown). Combined with the highly efficient recovery of bacteria from the digesta samples, the efficient lysis achieved with this protocol results in bacterial community DNA samples that are presumed to be representative of the bacterial populations present in the digesta from the chicken GI tract. Thus, the procedures developed here provide sound samples, not only for the community analysis described below, but also for any other DNA-based analysis (PCR, hybridizations, etc.) that might be used for the characterization of bacterial communities in the chicken GI tract.

Percent G+C profiles of the digestal communities. To obtain a profile of ileal and cecal digesta bacterial communities based on percent G+C content, 100 \mu g of each DNA sample was subjected to cesium chloride-bisbenzimidazole gradient analysis as described previously (11). Since there was no residual protein in these highly purified DNA preparations, DNA quantitation was based on $A_{280}$ which minimizes background absorbance resulting from the cesium chloride gradient itself and unbound bisbenzimidazole. Determination of the percent G+C content represented by each gradient fraction was accomplished by regression analysis ($r^2 > 0.99$) of data obtained from gradients containing standard DNA samples of known percent G+C composition (Clostridium perfringens, Escherichia coli, and Micrococcus lysodeikticus). Fractionation of total bacterial community DNA based on percent G+C content has previously been used to analyze bacterial communities and how they respond to changing conditions in soils (10), bioreactors (12), and cricket hindgut (30). The data reported here extend that analysis to studies of the bacterial communities in the GI tracts of broiler chickens. To assess variability and reproducibility in this system, replicate samples of bacterial community DNA isolated from ileal and cecal digesta of 4-week-old broiler chickens were subjected to cesium chloride-bisbenzimidazole gradient analysis. The data indicate that replicate samples from each compartment show similar profiles, while the bacterial communities in the ileal and cecal compartments were substantially different from one another (Fig. 2). While the pooling of digesta from two birds may have resulted in some averaging of differences in bacterial communities between individual birds, the replicate samples analyzed were independent replicates, and the data thus suggest that birds raised together under identical conditions have similar bacterial community compositions in their GI tracts (Fig. 2).

Numerous bacterial species have been characterized from the GI tract of the chicken by selective plating and subsequent identification by biochemical profiles (1, 3, 4, 7, 8, 14, 17, 23, 34, 37).
28, 29, 35). Such studies clearly demonstrate the presence of the selected bacterial groups, but probably do not accurately depict the total bacterial community in question. Figure 3 shows ranges of percent G+C content in the DNA of some of the genera which have been reported to be present in the GI tract of the chicken. The ileal and cecal bacterial communities illustrated by the percent G+C profiles (Fig. 2 and 4) may be, but are not necessarily, composed of the members of the bacterial genera listed. Speculation regarding the identity of organisms represented by these profiles is useful in guiding future studies, but to truly demonstrate whether a particular organism or group of organisms is present in a given region of the bacterial community profile requires additional DNA hybridization or ribosomal DNA analyses as reported previously (12, 33).

Changing digestive communities by live-fed bacteria. To determine whether it is possible to alter the community in the GI tract and detect such changes in community structure by using this DNA-based community analysis, newly hatched chicks were inoculated with a single dose either of bacteria from the cecal contents of commercially raised, free-range chickens or \textit{C. perfringens}. \textit{C. perfringens} (1:1 mixture of ATCC 13124 and ATCC 3626) was grown overnight anaerobically at 37°C in RCM medium (Difco, Detroit, Mich.). The bacterial cells were collected by centrifugation at 20,000 \( \times \) g and then resuspended in anaerobic 0.9% NaCl solution. Approximately 10\(^6\) bacteria were introduced into 0.1 ml of solution. Approximately 10\(^6\) bacteria were introduced into the crop of the broiler chicks as described above. Bacterial numbers in the inocula were determined by direct microscopy. Following bacterial inoculation, the birds were raised under a corn-based diet, and then the cecal bacterial community DNA was recovered and analyzed. The bacterial community profiles were used to inoculate 50 ml of anaerobic brain heart infusion solution. Approximately 10\(^8\) bacteria were introduced as 0.1 ml aliquots. An aliquot was used to inoculate 50 ml of anaerobic brain heart infusion medium (LAB M: Bury, United Kingdom) in a tightly stoppered serum bottle. The culture was grown static overnight at 37°C. The bacteria were harvested by centrifugation at 20,000 \( \times \) g and then resuspended in anaerobic 0.9% NaCl solution. Approximately 10\(^8\) bacteria were introduced as 0.1 ml of an appropriately diluted bacterial suspension directly into the crop of the broiler chicks as described above. Bacterial numbers in the inocula were determined by direct microscopy. Following bacterial inoculation, the birds were raised under identical conditions for 10 days on a standard, antibiotic-free, corn-based diet, and then the cecal bacterial community DNA was recovered and analyzed. The bacterial community profiles from the ceca (cecal digesta of six chickens were pooled) of differently inoculated broiler chickens were different from each other and from those of the uninoculated control birds (Fig. 4).

Compared to the percent G+C profile from the uninoculated broiler chickens, those inoculated with \textit{C. perfringens} showed an increase in the relative abundance of DNA, and hence bacteria, having 25 to 40% G+C content, and a decrease in the relative abundance of bacteria whose DNA is in the 42 to 55% G+C range (Fig. 4). Although no subsequent confirming analyses were performed, this is consistent with an increase in the abundance of clostridia, campylobacteria, and enterococci or perhaps unculturable bacterial populations having the indicated percent G+C content. The cecal bacterial community from chickens inoculated with the mixed bacterial populations from commercially raised birds showed a relatively large increase in bacterial populations having 55 to 75% G+C content and a corresponding decrease in the relative abundance of bacteria populations having 50 to 55% G+C content. These data are consistent with an increase in bifidobacteria and propionibacteria (Fig. 3 and 4), although no confirming analysis was performed.

Profiling of the DNA from the total GI tract bacterial community according to its percent G+C content as described here is totally independent of the culturability of the component bacteria. Further studies employing DNA hybridization or quantitative PCR with specific primers would help confirm the presence and abundance of specific bacterial groups in the total microbial community of the chicken GI tract (11, 18, 31, 33). However, these approaches are dependent on reference bacteria and therefore on previous strain isolation under laboratory conditions. Assessment of the relative contribution of uncultured organisms to the total bacterial community is an arduous task requiring extensive molecular analyses, including primer and probe design, PCRs, cloning, sequencing, and nucleic acid hybridization experiments. With the approaches described here, we have at hand a relatively rapid community-level analysis which generates data in the form of DNA abundance versus percent G+C content. This technique provides a window on population dynamics in the community to guide future experiments related to the microbial ecology of the GI tracts of chickens.
