[1] We examined the response of terrestrial carbon fluxes to climate variability induced by the El Niño–Southern Oscillation (ENSO). We estimated global net primary production (NPP) from 1982 to 1999 using a light use efficiency model driven by satellite-derived canopy parameters from the Advanced Very High Resolution Radiometer and climate data from the National Centers for Environmental Prediction/National Center for Atmospheric Research reanalysis project. We estimated a summed heterotrophic respiration and fire carbon flux as the residual between NPP and the terrestrial net carbon flux inferred from an atmospheric inversion model, excluding the impacts of land use change. We propose that for global applications this approach may be more robust than traditional, biophysically based approaches of simulating heterotrophic respiration. NPP interannual variability was significantly related to ENSO, particularly at lower latitudes (22.5°N–22.5°S) but was weakly related to global temperature. Global heterotrophic respiration and fire carbon fluxes were strongly correlated with global temperature (7.9 pgC/°C). Our results confirm the dependence of global heterotrophic respiration and fire carbon fluxes on interannual temperature variability and strongly suggest that ENSO-mediated NPP variability influences the atmospheric CO₂ growth rate.

1. Introduction

[2] The willingness of world governments to limit the emission of greenhouse gasses is partially limited by scientific uncertainty regarding the interactions among terrestrial ecosystems, climate variability and trends, and atmospheric CO₂ concentrations. For example, coupled climate/carbon cycle models indicate positive feedbacks between respiration and climate change will occur in the 21st century [Cox *et al.*, 2000; Dufresne *et al.*, 2002] but the magnitude of these responses is highly uncertain [Friedlingstein *et al.*, 2003]. Developing a clear understanding of the relationship between past climate variability and ecosystem processes

will provide an opportunity to increase our confidence in future carbon cycling-climate scenarios [Reichenau and Esser, 2003; Schaefer *et al.*, 2002; Potter *et al.*, 2003].

[3] In addition to understanding the impacts of long-term secular climate changes, it is crucial to analyze the importance of cyclic climatic phenomenon for interannual variability in carbon cycle processes. In particular, because of pervasive teleconnections, the El Niño–Southern Oscillation (ENSO) is likely to have a strong impact on the global carbon balance [Foley *et al.*, 2002; Botta *et al.*, 2002; Potter *et al.*, 2003]. In spite of some controversy [Cobb *et al.*, 2003], evidence suggests that the frequency of warm phase (El Niño) ENSO events has increased since the 1980s [Trenberth and Hoar, 1997], implying that a similar systematic shift in the global carbon balance may have occurred simultaneously.

[4] The response of the global carbon cycle to such variations in ENSO strength can be inferred from atmospheric CO₂ observations. Bacastow [1976] first showed significant correlation between the Southern Oscillation Index (SOI) and CO₂ growth rates at Mauna Loa and the South Pole. Using an expanding network of atmospheric observation sites [Conway *et al.*, 1994], scientists developed a consensus regarding the response of terrestrial ecosystems to ENSO events [Battle *et al.*, 2000; Le Quéré *et al.*, 2003]:

during El Niño, carbon sequestration is reduced on land and increased in oceans; the reverse is true in the La Niña phase. Since the carbon cycle reaction to ENSO events is stronger in terrestrial systems than in oceans, El Niños result in a net global carbon release to the atmosphere. Although the exact magnitude is uncertain, evidence from atmospheric inversion and ocean models [Le Quéré et al., 2003] indicates that the interannual variation of terrestrial ecosystem carbon processes is in phase with ENSO events.

[5] Global carbon cycle models incorporating climate response functions are used to clarify the mechanisms behind these responses. In the terrestrial portion of these models, net CO₂ uptake is the difference between net primary production (NPP) and heterotrophic respiration (HR), each of which is a function of climatic and vegetation processes and properties. Using a simple empirical model and variations in temperature and precipitation, Dai and Fung [1993] explained at least half of the missing sink for 1950–1984. This approach, however, provides little mechanistic understanding of the processes controlling carbon sequestration or emission. In process models, which can provide a mechanistic understanding of ecosystems responses, it is possible to derive correct net CO₂ from errors in both NPP and HR [Running and Hunt, 1993].

[6] An alternative approach, pursued here, is to employ a quasi-mechanistic model for NPP and to obtain heterotrophic respiration as the residual between NPP and inverse estimates of net carbon balance. Using this approach, our goal is to assess the spatiotemporal response of NPP and heterotrophic respiration to climatic variability, especially ENSO strength.

2. Data and Methods

[7] We calculated monthly global 0.5° NPP from 1982 to 1999 (0.5° is a common resolution for global carbon models [Cramer et al., 1999]) using the light use efficiency (LUE) approach [Monteith, 1972]. In our model, Gross Primary Production (GPP) is calculated as

$$GPP = \varepsilon * FPAR * PAR, \quad (1)$$

where ε is LUE (g MJ⁻¹), PAR is photosynthetically active radiation (MJ), and FPAR is the fraction of PAR absorbed by plant canopies (0 to 100%). Temperature and water constrain photosynthesis as follows:

$$\varepsilon = \varepsilon_{\max} * W(VPD) * T(T_{\min}), \quad (2)$$

where $\varepsilon_{\max}$ is the maximum biome-specific LUE, W is a limitation factor that is a function of Vapor Pressure Deficit (VPD, Pa), and T is a limiting factor of minimum temperature ($T_{\min}$). We used an 11-biome landcover map based on work by DeFries and Townshend [1994] and a look-up table optimized from the Biome-BGC model [Running and Hunt, 1993; Thornton, 1998; White et al., 2000] to define the global distribution of $\varepsilon_{\max}$, W and T . In the optimization scheme, VPD acts as a proxy for the overall plant water stress including rainfall deficits as well as low humidity. As a consequence, our GPP model does not use precipitation data.

[8] We predicted autotrophic respiration by first calculating various ecosystem carbon pool sizes using biome-

specific allometric equations based on leaf area index (LAI) and subsequently by applying exponential temperature functions. We then calculated NPP as the difference between GPP and autotrophic respiration (equation (3))

$$NPP = GPP - R_{\text{auto}}(LAI, T), \quad (3)$$

where R_{auto} is the autotrophic respiration. Details of the NPP calculation algorithm are available in work by Running et al. [2000] and Nemani et al. [2003].

[9] LAI and FPAR data sets used in this study were generated using a 3-D radiative transfer model [Myneni et al., 1997] in conjunction with monthly AVHRR (Advanced Very High Resolution Radiometer) Normalized Difference Vegetation Index (NDVI). For an extended discussion of the data sets and methods, please see Nemani et al. [2003, supplement].

[10] We used the National Centers for Environmental Prediction/National Center for Atmospheric Research Reanalysis data (hereafter referred to as reanalysis) [Kalnay et al., 1996; Kistler et al., 2001] for climatic inputs. The reanalysis uses a T62/28-level spectral model in the assimilation system. Although the reanalysis contains systematic spatiotemporal biases in many variables caused by cloud/moisture parameterization, prescribed surface parameterization, complex topography, etc., it is considered robust enough for use in studies investigating interannual ENSO variation [Mo and Higgins, 1996; Janowiak et al., 1998; Yang et al., 1999; Ribera and Mann, 2002]. Extensive verification of reanalysis data was conducted using ancillary data sets of solar radiation and air temperature, two of the main variables in our NPP modeling, and reported by Nemani et al. [2003, supplement].

[11] Accurate modeling of the spatiotemporal distribution of HR is extremely difficult because of at least three reasons. First, soil carbon pools can only be measured at specific sites, while aboveground carbon can be estimated from satellite data. For example, LAI or above ground biomass can be estimated from satellites using radiative transfer models. Next, temperature (often assessed using a Q_{10} or other temperature-based approach [Lloyd and Taylor, 1994]), precipitation [Raich and Schlesinger, 1992], GPP [Janssens et al., 2001], and disturbance history [Wardle et al., 2003] all influence HR, but there is still considerable uncertainty in spatially explicit estimates of these variables. Knorr [2000] attributes the uncertainty of the interannual variability of soil respiration to Q_{10} and litter turn over time, and both of them are highly variable in space. Finally, process-based models often assume that HR is in equilibrium with NPP over some period, but the selection of the period is arbitrary.

[12] Instead of attempting an explicit calculation, we used a three-step residual approach to estimate global HR. First, we obtained the net land CO₂ balance estimated from the Scripps Oceanography Institute inversion model (based on inverse techniques using a double deconvolution of CO₂ and $\delta^{13}\text{C}$ from nine stations in the Pacific Ocean basin [Keeling et al., 2001; Le Quéré et al., 2003]). Since a CO₂ observation network sufficient to obtain a robust time series of regional carbon uptakes is lacking [Bousquet et al., 2000], this estimate is valid for global fluxes only. Second, we subtracted this net land CO₂ balance from our simulated

NPP, yielding our initial estimate of global HR. Third, we subtracted land use carbon estimates [Houghton and Hackler, 2002] because the net land CO₂ signal includes carbon emissions from land use change and we were attempting to isolate HR. This yielded a land use corrected value for global HR.

[13] Although biomass burning contributes to the interannual variability of carbon release [Langenfelds *et al.*, 2001; Page *et al.*, 2002; van der Werf *et al.*, 2004], atmospheric observations of carbon emissions from global fires are not available for the 1980s. Consequently we did not subtract fire carbon emissions and our carbon release term represents the sum of HR and carbon released from fires.

[14] Using this model construct, we conducted four separate analyses. First, in order to separate the influence of vegetation structure and phenology versus climate factors, we conducted the following three NPP simulations: (1) changing vegetation (FPAR and LAI) and climate (VPD, temperature and radiation); (2) changing vegetation and constant climate; and (3) constant vegetation and changing climate.

[15] Second, we analyzed NPP anomaly patterns for El Niño periods. Trenberth [1997] defined an El Niño when 5-month running means of sea surface temperature anomalies in the El Niño 3.4 region (5°N–5°S, 120°W–170°W) exceeded 0.4°C for 6 months or more; by this method, El Niños occurred in 1982–1983, 1986–1988, 1991–1992, 1993, 1994–1995, and 1997–1998. Because of their unusual nature and the 1991 Pinatubo eruption, we did not consider the 1991 to 1995 El Niños. In order to isolate the lagged response of NPP to ENSO, as measured by the Multivariate ENSO Index (MEI [Wolter and Timlin, 1998]), we detrended monthly NPP and then created averaged monthly NPP anomalies for low (22.5°N–22.5°S), mid (47.5°N–22.5°N), and high (90°N–47.5°N) latitude regions. On the basis of these results, we then conducted a climate anomaly analysis for the latitudinal region contributing most to global NPP anomalies.

[16] Third, we assessed the detrended global response of climatic variables (temperature, VPD, and radiation) and NPP to 6-month lagged MEI. In reality, the time lag is variable and should be short in regions close to the equatorial Pacific where MEI is calculated. However, we used a fixed 6-month lag for simplicity, and the difference of the regression result between no time lag and 6-month lag was small (not shown here). We removed seasonal autocorrelation with a 12-month running average, although removing autocorrelation can remove low-frequency correlations [Potter *et al.*, 2003], and then used linear regressions with a 2-tailed *t* test of significance for each pixel. There were 166 degrees of freedom [(18 – 1 (running average) – 3 (Pinatubo effected year)) * 12 (monthly interval) – 2 (two-tailed test)].

[17] Fourth, we analyzed trends in the interannual variability of carbon release (HR plus fire), NPP, and net carbon balance in response to ENSO cycles. We finally assessed the relationship between global temperatures and these global NPP and carbon release anomalies. Here we used the highly quality controlled, updated, and cited [Intergovernmental Panel on Climate Change, 2001] global temperature data from Jones *et al.* [2001]. These data, which include both land and ocean, are strongly in phase with land temperature

Figure 1. Time series of global NPP anomaly (solid line), global CO₂ growth rate anomaly (dashed line, inverted scale), and MEI (dotted line). High MEI represents ENSO warm phase. NPP anomaly is calculated from a 12-month running total of monthly global NPP.

and thus provide a useful and independent alternative to further use of the reanalysis data.

3. Results and Discussion

3.1. Interannual Variation of NPP, ENSO, and CO₂ Growth Rate

[18] In our simulations, the 1982 to 1999 interannual variability of terrestrial NPP was predominantly determined by climatic variations, not vegetation dynamics (Figure 1). Similarity between the cycles of MEI and NPP was highest in the changing vegetation + changing climate and constant vegetation + changing climate simulations. NPP variation in the changing vegetation + constant climate simulation, wherein the effects of variable FPAR and LAI were disconnected from simultaneous climate variability, was dramatically different, with lower interannual variability and a more apparent long-term trend of increasing NPP.

[19] The strong relationship between the CO₂ growth rate and NPP variations in changing vegetation + changing climate and constant vegetation + changing climate experiments, suggests a coherence between factors that regulate net ecosystem exchange (NEE) and NPP. There is a discrepancy between the MEI and the CO₂ growth rate from 1991 to 1993 when climatic effects from the Mount Pinatubo volcanic eruption overwhelmed the ENSO perturbation [Jones and Cox, 2001; Reichenau and Esser, 2003].

Figure 2. Summary of NPP and atmospheric CO₂ responses during El Niño years (1982–1983, 1986–1987, and 1997–1998). NPP anomalies are shown for each latitudinal band (dotted black line, 90°N–47.5°N; dashed black line, 47.5°N–22.5°N; and solid black line, 22.5°N–22.5°S) and globally (green line). Red line is CO₂ growth rate anomaly; blue line is MEI.

3.2. Temporal Response of NPP to ENSO

[20] Our analysis of the three El Niño periods suggests that global NPP began to decline about 6 months after the initiation of increasing MEI and that these global NPP decreases then affected the global CO₂ growth rate (Figure 2). Initiation of the secular decrease in the global NPP anomaly occurred in August/September, about 6 months after the initial MEI increase in February/March. The CO₂ growth rate anomaly (calculated by subtracting annual values from the mean CO₂ growth rate from 1982 to 1999 (1.55 ppm/yr) and multiplying 2.1 pgC/ppm) began a sharp increase around September of the first year and peaked during the boreal summer of the second year. The maximum first derivative of the CO₂ growth rate was essentially concurrent with the linearly decreasing global NPP (August/September of first year to May/June of second year). As other factors such as HR, biomass burning, fossil fuel production, land cover change, and oceanic uptake all affect the CO₂ growth rate, it is difficult to compare directly global NPP and CO₂ growth rate. Although Rayner *et al.* [1999] suggested that oceanic carbon uptake causes the negative first-year CO₂ growth rate anomaly our results imply that global NPP also contributes to negative CO₂ growth rate in much of the first year of El Niño events and higher rates thereafter.

[21] Furthermore, it appears that low-latitude tropical regions (22.5°N–22.5°S) were largely responsible for these effects. From January through September of the first year of El Niños, the NPP anomaly of low-latitude regions was virtually identical to the global anomaly; patterns for the duration of the El Niño were also similar. With the exception of a moderate decline in May and June of the second year, the NPP anomaly of high-latitude regions (90°N–

47.5°N) was essentially flat. Middle latitude regions (47.5°N–22.5°N) were similar to high-latitude regions and showed a minimum NPP anomaly in August of the second year. Vegetation activity in middle and high-latitude regions peaks in boreal summer, producing a maximal carbon release lagging the low-latitude response. The minimum of the global NPP anomaly therefore occurred during early summer of the second year.

Figure 3. Anomalies of (a) temperature, (b) VPD, and (c) short-wave radiation over tropical regions during El Niño years (1982–1983, 1986–1987, and 1997–1998). Solid line represents a running mean of monthly values shown as dotted line.

Figure 4. Six-month lagged linear regressions of (top) temperature, (middle) VPD, and (bottom) short-wave radiation versus MEI. Values from 1991 to 1993 period are excluded. Data that have 95% significance level are shown.

[22] Our results agree with other process-based model studies showing that the interannual variations in CO_2 growth rate are largely regulated by the interannual variations of NEE in the tropics [Kaduk and Heimann, 1994; Kindermann et al., 1996; Gérard et al., 1999]. Inverse models of CO_2 measurements also show similar results [Bousquet et al., 2000].

[23] On the basis of its role in explaining the global El Niño–NPP signal (Figure 2), we investigated the climatic component of tropical El Niños (Figure 3). While the interpretation of these results is limited by the use of only three El Niño events, possible underestimation of fire effects

[Reichenau and Esser, 2003], and uncertainty in the interannual variability of atmospheric transport [Dargaville et al., 2000], a coherent climatic pattern is evident. The temperature anomaly was negative from January to June of the first year, and was greater than 0.5°C for most of the second year. The VPD anomaly was also negative before July of the first year, and then became positive with the exception of drops around December of both years. The anomaly of short-wave radiation was irregular but tended to be positive before October of the first year and negative thereafter. In summary, the climate variables show two patterns: (1) high NPP in the first year of El Niños occurred in conjunction with cooler temperatures, low VPD, and high radiation, and (2) low NPP during the second year occurred in conjunction with warm temperatures, high VPD, and average or low radiation.

3.3. Spatial Response of Climate and NPP to ENSO

[24] Figure 4 shows the spatial patterns of regressions between climatic variation (temperature, VPD and short-wave radiation) and 6-month lagged MEI. In our study, as in others [Ropelewski and Halpert, 1987; Hoerling and Kumar, 2003], global climate exhibited coherent spatial responses to MEI strength. Generally, tropical regions and northern North America warmed with increasing MEI. On the contrary, southwestern North America, northeast Asia, and southern South America cooled in the warm phase. In the warm phase, VPD increased in southern and northwestern Africa and large portions of the Amazon basin but decreased in southwestern North America, Argentina, the Middle East, and Central Africa. Short-wave radiation had a more extensive negative relationship with MEI but increased in the Amazon and south central North America during warm phases.

[25] MEI variation also strongly impacted global carbon cycle (Figure 5). In most regions, increasing MEI was negatively correlated with NPP. This pattern was especially strong in northern South America, Africa below the Sahel, and eastern North America. The general tendency of NPP to decrease in the warm phase reduced global NPP by more than 2 pgC/yr in 1997/1998 (Figure 1). Only northwestern

Figure 5. Six-month lagged linear regressions of NPP and MEI (1991 to 1993 excluded) showing the global impacts of ENSO on terrestrial NPP. Data that have 95% significance level are shown.

Figure 6. Anomaly of global NPP (dashed line) and carbon release (sum of HR and carbon released from fires, solid line) from 1982 to 1999. The difference between NPP and HR is carbon balance from Keeling *et al.* [2001]. Horizontal lines show net carbon release, and checkered areas show uptake. MEI is shown in gray scale, where darker shades represent higher MEI (warm phase).

North America and Argentina had strong positive relationships with MEI. These warm phase NPP increases were related to warmer temperatures in northwestern North America and cooler temperatures and reduced VPD in Argentina.

[26] Jones *et al.* [2001] and Schaefer *et al.* [2002] conducted similar analyses for GPP (not for NPP as in this study). As for this study, these authors also found warm phase decreases GPP in India and Australia due to drought and increases GPP in northwestern North America due to favorable moisture regimes. However, we found a decrease in NPP over western Africa and parts of Amazonia while others found an increase [Jones *et al.*, 2001] or no change [Schaefer *et al.*, 2002]. These differences may be a result of different climate data sets, NCEP/NCAR reanalysis data (this study), HadCM3LC [Jones *et al.*, 2001] and ECMWF reanalysis data [Schaefer *et al.*, 2002].

[27] In the northern Amazon basin, our results showed no significant change while Jones *et al.* [2001] showed a strong decrease. Climate data in all cases showed drought in the warm phase, so the different NPP response is from model sensitivity to drought. These model-dependent responses were reported especially in the northwestern Amazon basin. For example, Tian *et al.* [1998] showed no significant change in the northwestern part of Amazon basin, but Foley *et al.* [2002] showed a decrease. Differences in model parameterization of rooting depths appear to be one of the main drivers leading to different NPP responses [Nepstad *et al.*, 1994].

3.4. Net Carbon Balance From Atmospheric Inversion

[28] Figure 6 shows the interannual variability of NPP and HR. Large global net carbon releases occurred during or soon after strong El Niños (1982–1983, 1986–1987, and 1997–1998) while major net uptake occurred during periods of low MEI or La Niña periods. Some process-based studies showed that HR anomalies are smaller than NPP anomalies [Kindermann *et al.*, 1996; Gérard *et al.*, 1999],

but other studies [Knorr, 2000; Cao *et al.*, 2002] showed almost similar magnitudes. Whether NPP anomalies exceed HR anomalies is largely dependent on model parameterization (especially Q_{10}) for process-based models. In our study, NEE anomalies were within 2 pgC/yr, and were slightly larger than NPP.

[29] We tested, using a two-tailed test, the significance of the trends in NPP, HR and net carbon balance from the deconvolution. There was no statistically significant trend ($p > 0.1$) in HR, whereas NPP increased significantly ($p < 0.05$). The carbon balance from the deconvolution showed a moderate trend ($0.05 < p < 0.1$) in carbon uptake. If we included a CO_2 fertilization effect in our simulations the NPP (HR) trend would increase (decrease). Therefore it appears that there can be no trend in HR, and the moderate

Figure 7. Correlation between global temperature anomalies [Jones *et al.*, 2001] and anomalies in (a) NPP and (b) HR plus fire. Numbers in Figure 7b indicate the years (1982–1999).

trend in carbon uptake by land can be attributed only to increasing NPP. Previous modeling studies estimated a significant increasing trend in HR in the 1980s and 1990s [Cao *et al.*, 2002], but acclimation may negate the increase trend. [Luo *et al.*, 2001; Cao *et al.*, 2002].

[30] We correlated the NPP and HR with anomaly of the climate components to explain which component dominates in global carbon cycle (Figure 7). Anomalies of carbon release had a positive correlation with global temperature ($r = 0.67$, $p < 0.005$) while NPP anomalies had no correlation with global temperature ($r = 0.33$, $p > 0.1$). Using different methods, others [e.g., Raich *et al.*, 2002] have shown a similar temperature dependency of HR. We also checked the relationship between carbon release and VPD, precipitation, and radiation but found no meaningful relationship.

[31] El Niños are associated with extensive biomass burning and subsequent large pulses of carbon release. For example, Langenfelds *et al.* [2002] estimated carbon release by biomass burning of 0.6–3.5 pgC/yr in 1994/1995 and 0.8–3.7 pgC/yr in 1997/1998. Van der Werf *et al.* [2004] estimated a yearly anomaly of 0.59 pgC/yr for 1997 and 1.17 pgC/yr for 1998. Thus, while the slope of the regression in Figure 7b is 7.9 pgC/degree, the regression of HR without fire would be smaller. Overall, our results indicate that global HR, but not NPP, is strongly influenced by temperature variability.

4. Conclusion

[32] A large suite of ENSO-influenced climate variables strongly influences interannual variability in NPP [Nemani *et al.*, 2003]. There is considerable spatial variability in these controls and consequently in the magnitude and direction of El Niño impacts on terrestrial NPP. On the other hand, heterotrophic respiration is primarily sensitive to temperature. We observed that the global CO₂ growth rate appears to be highly responsive to global and especially tropical NPP, which in turn has a 6-month lagged relationship with MEI. A number of factors besides interannual climate variability affect global carbon cycling including decadal/century-scale climate oscillations [Botta *et al.*, 2002], land use/land cover changes and socioeconomics and technology. A better understanding of their relative contributions to the ever-increasing atmospheric CO₂ concentrations is clearly needed.
